(Manuscript received 29. 11. 1977, in revised form 3. 2. 1978)

## Abstract

A method is presented to get optimal numerical filters that does not affect the convergence-properties of the difference-approximation. Results are shown and compared with the properties of the corresponding Shapiro filters.

**Zusammenfassung:** Konstruktion optimaler numerischer Filter zur Lärmdämpfung in numerischen Simulationsmodellen

Ein Verfahren zur Gewinnung optimaler numerischer Filter, die die Stabilität und Konsistenz des Differenzenverfahrens nicht beeinflussen, wird dargestellt. Es werden verschiedene auf diese Weise konstruierte Filter angegeben und mit den entsprechenden von Shapiro verglichen.

**Résumé:** Construction de filtres numériques optimaux pour l'amortissement du bruit dans les modèles de simulation numérique

On présente une méthode pour obtenir des filtres numériques optimaux qui n'affectent pas les propriétés de convergence de l'approximation aux différences finies.

On compare divers filtres obtenus de cette façon avec les filtres de Shapiro correspondants.

## 1 Introduction

In simulating the general circulation of the atmosphere through finite difference techniques it is necessary to damp out small-scale perturbations with scales near the lower boundary of the models resolution. Otherwise the meteorological fields will eventually be destroyed by nonlinear instability, which is due to the aliasing effect (which can partly be avoided by a suitable difference scheme; ARAKAWA, 1970), by imbalances due to small-scale forcing terms (convection, mountains ...) and boundary effects. (PHILLIPS, 1959; ROECKNER, 1976).

The necessity of filtering short waves also appears in the finite element method (CULLEN, 1976), the pseudospectral method (MERILESS, 1974) and the spectral method (BATCHELOR, 1969).

There are different procedures for filtering:

- (1) Adding *diffusion-terms* to the equations. CULLEN (1976) and SHAPIRO (1971) have listed several possibilities;
- (2) Applying the *chopping-method*, which consists of an expansion of meteorological fields in orthogonal functions with a recombination omitting high wavenumbers. In spherical grid representation a convenient way is the Fourier filter, where a harmonic analysis along latitudinal circles is performed and all wavelengths that are shorter than for instance  $4 \Delta x$  are disregarded, where  $\Delta x$  is the zonal grid interval. (See PHILLIPS, 1959; WILLIAMSON, 1974; MERILEES, 1974);

- (3) *Numerical filtering.* In this method each value of a gridpoint is replaced by an average formed with surrounding gridpoint values (for an exact definition, see Section 2). The first numerical filter in meteorology was presented by SHUMAN (1958) and applied by WALLINGTON (1962) in a numerical weather prediction model.  
 A special class of numerical filters was introduced by SHAPIRO (1970) and adopted among others by FRANCIS (1975), CULLEN (1976) and MUDRICK (1976).
- (4) *Diffusive finite difference schemes* possess a “built in” mechanism of damping short waves. The Lax-Wendroff scheme, the Euler method and the “upstream” differencing should be mentioned in this context (see e.g. KREISS and OLIGER, 1973).

The discussion, which of the four methods is the best, has not yet come to an end. In what follows, suitable numerical filters similar in their characteristics to those described by SHAPIRO (1975), will be presented.

When applying a numerical filter one must ensure that it does not affect the convergence properties of the difference approximation. Therefore, the filter must be a consistent approximation of the identity operator and must be stable, i.e. no wave component may be intensified. A series of such filters were proposed in the past, e.g. by SHUMAN (1958) and SHAPIRO (1971, 1975), they are, however, not ‘optimal’ in the sense, that the best scale selection with a certain amount of computation is achieved.

The necessary range of scale selectivity depends on the model’s difference formulation. If the latter does not exclude aliasing, the filters should damp about the upper third of the wavenumber range (ORSZAG, 1971). When, on the other hand, employing a difference scheme with de facto no aliasing (Arakawa-type schemes) the filter should only affect the very high wavenumbers.

We will describe a method to get ‘optimal’ filters that are especially suitable for schemes without aliasing and display some results. It is planned to report in a subsequent paper, how the filters work in a general circulation model.

The problem of constructing such filters will be regarded as an optimization problem *with* (linear) constraints. This is a wellknown problem in applied mathematics and can be solved by known methods.

Already formerly the problem of constructing filters was interpreted as an optimization problem without constraints, i.e. as an approximation problem. However, filters obtained in this way were in general not stable as they were not aimed at guaranteeing computational stability in numerical simulation models. The first publication in this field was that of BLECK (1965), who used filters for analysis purposes. Independently of BLECK this idea was pursued in the geophysical literature by GALLI and RANDI (1967) with a subsequent correction by ZELEI (1971).

## 2 The formulation of the optimization-problem with linear constraints

### Definition:

Let the interval  $(0, 2\pi)$  be equally spaced into  $M$  pieces with gridlength  $\Delta x := \frac{2\pi}{M}$  ( $M$  an even number). Let  $D$  be the set of realvalued  $2\pi$ -periodic functions defined on the grid  $G := \{j \Delta x; j \in \mathbb{Z}\}$  and  $a_0, \dots, a_m$  real numbers ( $m \geq 1$ ). The map

$$T: D \rightarrow D$$

defined by

$$(Tf)(x) := a_0 f(x) + \sum_{j=1}^m a_j [f(x + j \Delta x) + f(x - j \Delta x)]$$

$(x \in G)$  is called a numerical filter of  $m$ -th order. The numbers  $a_0, \dots, a_m$  are called the *weights* of the filter  $T$ .

The possibility of application results from the following fact: As known every function  $f \in D$  can be expanded into a Fourier-sum:

$$f(x) = q_0 + \sum_{n=1}^{M/2} q_n^s \sin(nx) + q_n^c \cos(nx)$$

with  $q_{M/2}^s = 0$ . For every numerical filter there are numbers  $h(n) \in \mathbb{R}$  so that for every function  $f \in D$  the following representation is valid:

$$(Tf)(x) = h(0)q_0 + \sum_{n=1}^{M/2} h(n) [q_n^s \sin(nx) + q_n^c \cos(nx)]$$

(Note that for all real  $n \in \mathbb{R}$  the function

$$g_n : \mathbb{C} \rightarrow \mathbb{C}; g_n(x) := e^{inx}$$

is an eigenfunction of  $T$  with the eigenvalue

$$h(n) := a_0 + 2 \sum_{j=1}^m a_j \cdot \cos(nj \frac{2\pi}{M})$$

The function  $h$  is called the *response function* of the filter  $T$ . Each filter is determined by its response function.

A filter must have some *properties* if it shall be used in a numerical simulation model for the purpose of noise control:

- (1) The mean value (wavenumber 0) remains unchanged:

$$h(0) = 1$$

This property may be interpreted as being a consistent approximation of the identity operator.

- (2) None of the wave-components which are resolved by the model (thus the wavenumbers,  $0, 1, \dots, \frac{M}{2}$ ) is intensified.

$$h(n) \leq 1 \quad \text{for } n = 0, 1, \dots, \frac{M}{2}$$

This prescription may be defined as a stability property.

- (3) The filter causes no phase reversal, i.e. the response function is for all resolved wavenumbers non-negative.

$$h(n) \geq 0 \quad \text{for } n = 0, 1, \dots, \frac{M}{2}$$

- (4) The shortest resolvable component vanishes:

$$h\left(\frac{M}{2}\right) = 0$$

- (5) The modification of the meteorologically relevant wave range does not exceed a certain prescribed amount.

$$h(n) \geq r_n \quad \text{for } n = 0, 1, \dots, \frac{M}{2}$$

with some values  $r_n \in \mathbb{R}$ .

- (6) Moreover, all components except the very high wavenumbers remain mostly unchanged, i.e. with some norm  $\|\cdot\|$ :

$$\| \mathbf{1} - \mathbf{h} \| = \min !$$

Possible norms are for instance the “ $l_1$ -norm”

$$\| \mathbf{1} - \mathbf{h} \|_1 := \sum_n |1 - h(n)|$$

or the “ $l_2$ -norm”

$$\| \mathbf{1} - \mathbf{h} \|_2 := \sqrt{\sum_n (1 - h(n))^2}$$

With the notation

$$\underline{\beta}_n := (\beta_{n0}, \dots, \beta_{nm})$$

where

$$\beta_{ni} := \begin{cases} 1 & \text{if } i = 0 \\ 2 \cos(ni \Delta x) & \text{otherwise} \end{cases}$$

and

$$\underline{a} := (a_0, \dots, a_m)$$

we get the representation

$$(*) \quad h(n) = \underline{\beta}_n \cdot \underline{a}'$$

for all  $n$ . (The prime denotes the transposition of the column vector  $\underline{a}$  into a row vector.)

According to the representation (\*) we can reformulate conditions (1) to (6) and comprehend them:

$$(1') \quad \underline{\beta}_0 \cdot \underline{a}' = 1$$

$$(2') \quad \underline{\beta}_n \cdot \underline{a}' \leq 1 \quad \text{for } n = 1, \dots, \frac{M}{2} - 1$$

$$(3') \quad \underline{\beta}_n \cdot \underline{a}' \geq r_n \quad \text{for } n = 1, \dots, \frac{M}{2} - 1$$

$$(4') \quad \underline{\beta}_{M/2} \cdot \underline{a}' = 0$$

and

$$(P') \quad - \left( \sum_{n=0}^{M/2} \underline{\beta}_n \right) \cdot \underline{a}' \stackrel{!}{=} \min$$

or

$$(P'') \quad \underline{a} \cdot \left( \sum_n \underline{\beta}'_n \cdot \underline{\beta}_n \right) \cdot \underline{a}' - 2 \left( \sum_n \underline{\beta}_n \right) \cdot \underline{a}' \stackrel{!}{=} \min$$

The problem (1') to (4') with (P') or (P'') is a wellknown problem in applied mathematics. It is the so-called *optimization problem*. Conditions (1') to (4') are called the (linear) *constraints*, and the minimizing functional from (P') or (P'') is called the *target function*.

In the case of (P') the problem is said to be *linear* for the target-function has the form

$$\underline{c} \cdot \underline{a}'$$

with some vector  $\underline{c}$ . The case (P'') is called *quadratic*, because there exist a matrix  $\underline{\underline{A}}$  and a vector  $\underline{c}$  so that the target-function may be written in the form

$$\underline{a} \cdot \underline{\underline{A}} \cdot \underline{a}' + \underline{c} \cdot \underline{a}'$$

There are methods to decide whether there exist solutions of the optimization problem (e.g. if  $r_n = 1$  for  $n = 1, \dots, \frac{M}{2} - 1$ , there is no solution.) and in case of existence how to get them.

For the linear case we have the so-called *simplex-method* which leads to the exact solution after a finite number of operations. Though the problem cannot be solved exactly in the nonlinear case, it can be well approximated. As we shall see later on, the quadratic formulation with  $(P'')$  is inferior to the linear one with  $(P')$ . (For the topic 'optimization problems' see e.g. COLLATZ and WETTERLING, 1971).

The filters being defined with the solution vector of the optimization problem will be called the *optimal numerical filter* (ONF) of m-th order. It will be denoted by

$$K_l^m$$

in the linear case and by

$$K_q^m$$

in the quadratic case. SHAPIRO's m-th order filter (SHAPIRO, 1975) will be denoted by

$$S^m$$

### 3 The linear case

In the linear case the lower boundary function  $r_n$  was chosen as the corresponding SHAPIRO filter, i.e. that of same order:

$$r_n := S^m(n)$$

In both the linear and the quadratic case  $M = 128$  was prescribed. For arbitrary order of  $m$  there exists a solution of the linear optimization problem and this one is more scale-selective than the SHAPIRO filter of same order, i.e. we get for all considered wavenumbers  $n$ :

$$S^m(n) \leq K_l^m(n) \leq 1$$

and

$$S^m\left(\frac{M}{2}\right) = K_l^M\left(\frac{M}{2}\right) = 0$$

For  $m = 1, 2$  and  $3$ , the maximal difference between  $K_l^m$  and  $S^m$  is less than  $0.1\%$ . Thus  $K_l^m$  and  $S^m$  are practically equal for  $m = 1, 2$  and  $3$ .

For  $m \geq 4$  the differences increase however, as can be seen from Table 1 and Figure 1.

The ONFs of order  $m \geq 8$  are even more scale-selective than SHAPIRO's of order  $m + 1$ , i.e.

$$S^{m+1}(n) \leq K_l^m(n) \leq 1 \quad \text{for } m \geq 8$$

For instance, one gets a better result if one works with the 17-points ONF  $K_l^8$  than if one applies the 19-point filter  $S^9$ . Furthermore, the application of the 15-point filter  $K_l^7$  yields essentially the same effect as the 17-point filter  $S^8$ .  $K_l^8$  is as good as  $S^{10}$  (see Figure 2).

In Table 2 the weights of the ONFs of order 4 up to 10 are listed. Though they are computed for  $M = 128$ , they are applicable for other values of  $M$ , too.

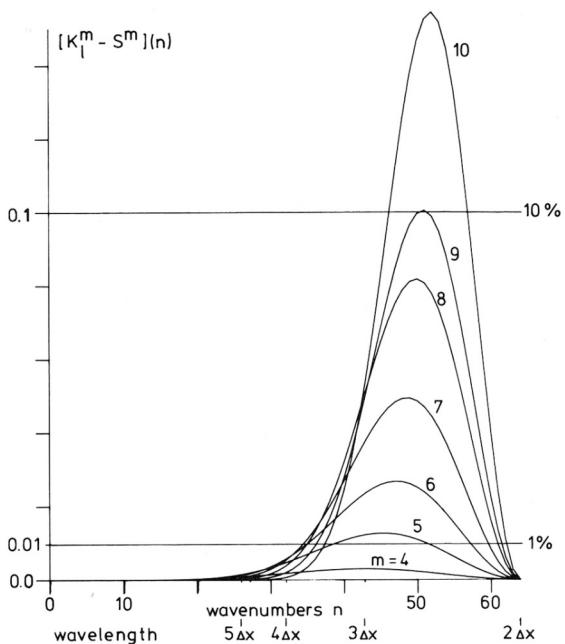

### 4 The quadratic case

As already mentioned there is no method giving the exact solution of the quadratic problem  $(1')$  to  $(4')$  and  $(P'')$ . Therefore one has to apply an approximation method. Cryer's method (see ECKHARDT

● **Bild 1**

Differenzen zwischen  $K_l^m$  und  $S^m$  für  $m = 4, 5, \dots, 10$

(1974)) was used. Solving such a nonlinear optimization problem is quite expensive regarding computer time. The essential factor is the number of constraints. Therefore, only every forth wavenumber in the constraints was considered. This simplification had no substantial influence on the solution given by the approximation method.

For the case  $M = 128$  and  $m = 4$ , one computation with 10,000 and one with 40,000 iterations were performed. The resulting vectors are listed in Table 3.

In Figure 3 the corresponding response-functions and the one of the 4-th order Shapiro filter are plotted. Our constructed filters seem to be rather good, but that is not really true for the following reason: Because the results given by the approximation method differ a little from the exact solution and do not fulfill the constraints exactly, the corresponding filters do not satisfy the conditions (1') to (4'). For instance, one has instead of

$$K_q^m(0) = 1$$

only

$$K_q^m(0) = 1 - \epsilon_0$$

with some small number  $\epsilon_0$ . Now, in a numerical simulation model the filter is frequently applied. The effect on the component with wavenumber 0 after k applications of the filter is:

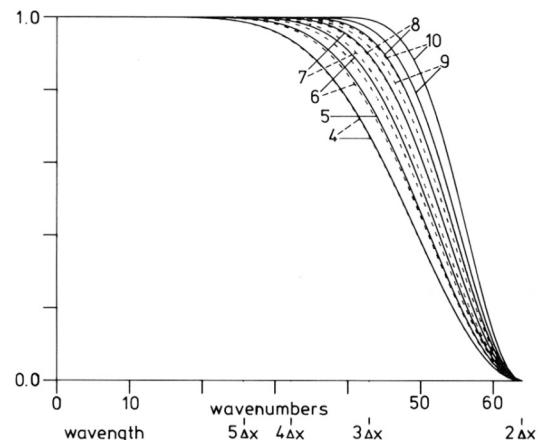

$$[K_q^m(0)]^k = (1 - \epsilon_0)^k \approx 1 - k\epsilon_0$$

● **Figure 2** The response-functions for  $K_l^m$  (solid lines) and for  $S^m$  (dashed lines),  $m = 4, 5, \dots, 10$

● **Bild 2** Die Response-Funktionen für  $K_l^m$  (durchgezogene Linien) und für  $S^m$  (gestrichelte Linien)  $m = 4, 5, \dots, 10$

If  $\epsilon_0 = 0.001$  and  $k = 240$  one gets a deviation of about  $0.24 = 24\%$ ! (A simulation over 5 days with filtering every 30 minutes requires 240 filterapplications.)

In Figure 4 the response-function of the 240-times application of  $K_q^4$  (40,000 iterations) and  $S^4$  is plotted. One can see that the ‘optimal’ filter is useless for our purposes.

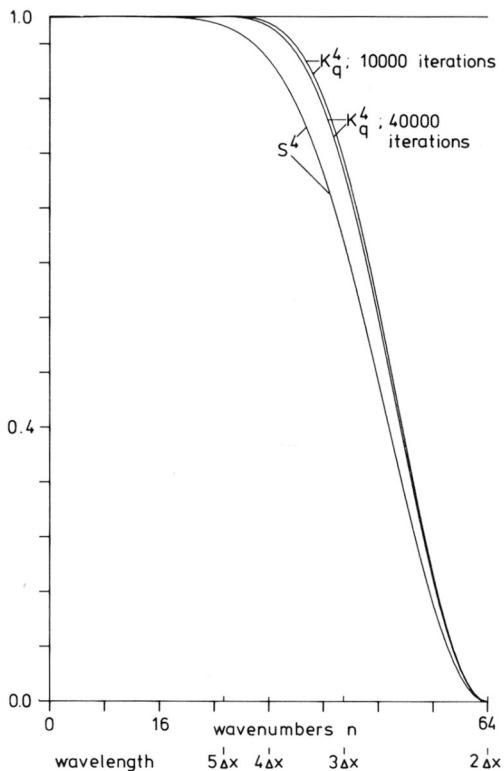

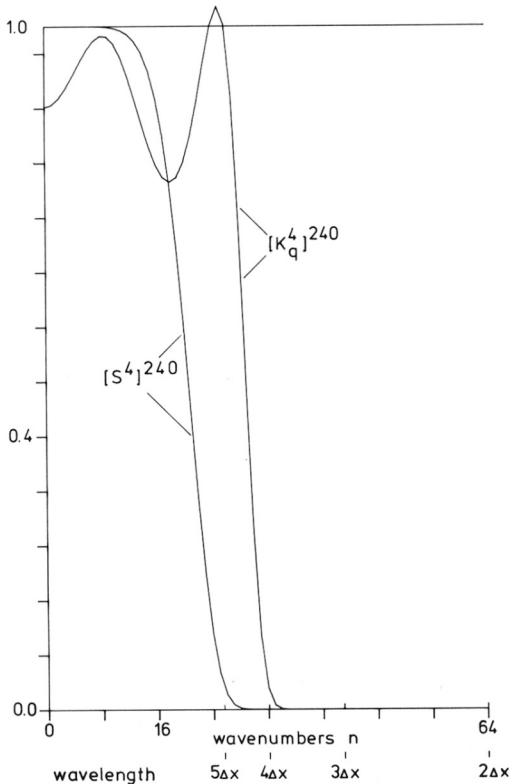

## 5 Conclusion

It turns out to be a successfull approach to formulate the problem of constructing filters for noise control as an optimization problem with linear constraints. The procedure working with the  $l_1$ -norm gives results superior to those known so far. For instance, the optimal 17-point-filter is a good as the 21-point-filter of Shapiro. On the other hand the nonlinear approach using the  $l_2$ -norm did not lead to filters appropriate for our purposes.
